Targeting the programmed death 1/programmed cell death ligand-1 (PD-1/PD-L1) immune checkpoint pathway in non-small cell lung cancer (NSCLC) with anti-PD-1 and anti-PD-L1 monoclonal antibodies led to durable responses for some patients and signalled to the oncology community that immunotherapy had finally arrived as an important anti-cancer therapy (1,2). Currently more than 200 clinical trials are on-going or actively recruiting targeting at least one aspect of the PD pathway in NSCLC. One of the major challenges in developing these clinical trials has been the need for standardized assays to measure tumoral PD-1 and PD-L1 expression, as a potential predictive biomarker of response (3,4).

Tumor PD-L1 expression is thought to contribute to immune evasion by binding to the inhibitory receptor PD-1 on T-cells leading to T-cell “exhaustion”. Interruption of the PD-1/PD-L1 signaling pathway can subsequently enhance T-cell responses by reversing exhaustion and eliciting anti-tumor activity (5). Improved responses to anti-PD-1 therapy have been seen in patients with higher PD-L1 expression in NSCLC (6-8). However, the value of PD-L1 expression in predicting patient responses to anti-PD-1/PD-L1 treatment remains controversial (9). The results using PD-L1 as a predictive biomarker for patient selection have been conflicting, in part, due to heterogeneity in PD-L1 expression and may be further exacerbated by the use of independent PD-L1 immunohistochemistry (IHC) assays, for anti-PD-1 mAbs Nivolumab and Pembrolizumab in clinical trials (10). Nivolumab clinical trials in NSCLC utilized the Dako 28-8 anti-PD-L1 antibody to identify three PD-L1 thresholds (≥1%, ≥5% and ≥10% of tumor cells) (7); whereas PD-L1 biomarker measurements in Pembrolizumab trials are calculated using the Dako 22C3 clone with two thresholds (≥1% and ≥50%) (11). The clinical activity of Nivolumab in a phase II trial appeared independent of tumoral PD-L1 expression as clinical responses were seen in PD-L1 negative patients. In contrast, Pembrolizumab treatment appeared to correlate with tumor cell expression of PD-L1 in over 50% of cells. Durvalumab, an anti-PD-L1 monoclonal antibody, uses the Ventana platform (Ventana SP263) as a diagnostic test for PD-L1 expression (12). The Ventana platform (SP142) is used with Atezolizumab, another anti-PD-L1 antibody. While the threshold for SP263 is set at ≥25% of PD-L1 positive tumor cells, SP142 also takes into account PD-L1 expression of immune cells resulting in a more complicated grading system (TC0-3 and IC0-3) (13).

Ratcliffe and colleagues have recently compared the use of three commercially available anti-PD-L1 IHC diagnostic assays in NSCLC (Dako 28-8, Dako 22C3 and Ventana SP263) (14). The main objective was to establish confidence in PD-L1 expression on patient tumor samples measured by these independent assays to enable flexibility in assay selection between laboratories and for comparison of results across clinical trials. The authors have provided analysis for PD-L1 expression on the largest cohort of NSCLC patient...
samples to date, 493 samples were cut into consecutive sections and evaluated by each of the antibody clones. All samples were assessed by the same pathologist and 200 of which were independently reviewed by a second pathologist.

The main important finding was the high concordance across PD-L1 assay platforms. The authors found correlative expression patterns of tumor membrane PD-L1 with an overall percentage agreement (OPA) of >90% recorded across assays and between variable expression level thresholds. OPA increased with higher expression cut-off levels, 91% at ≥1% up to 95% at ≥50% tumor membrane positivity. To fully compare the different anti-PD-L1 antibodies the group altered the scoring thresholds for the Ventana SP263 assay to include lower thresholds below 10% PD-L1 positive tumor cells. The SP263 and 22C3 assays showed a higher level of concordance at expression levels above 50% while a 25% positivity threshold for SP263 was equivalent to a 10% threshold with the Dako 28-8. These data highlight the importance of appropriate and comparable threshold values of PD-L1 expression. Thresholds should be calculated rigorously to ensure the largest percentage of patients show clinical efficacy and values need to be flexible depending on the type of combinational therapies tested. One aspect not currently addressed by the authors was whether assay agreement was independent of, or correlates with, patient tumor stage. Much of the patient demographic was disease stage I and II (80%), whereas collection of higher numbers of samples from stage III and IV patients would enable this to be investigated further. To fully harmonize PD-L1 assay platforms between clinical sites and across trials the reproducibility must be maintained at all disease stages.

Other studies have also sought to compare the use of anti-PD-L1 antibodies. Gaule et al. (15) examined whether 6 antibodies (SP142, E1L3N, 9A11, SP263, 22C3 and 28-8) could be used interchangeably to detect PD-L1 on an index tissue microarray (TMA). The study concluded that antibody clones could be used interchangeably to detect PD-L1 but that within tumor tissue samples inherent heterogeneity of PD-L1 expression increases assay variability across studies. This technical challenge was addressed by Ratcliffe et al. by serial sectioning of the same tissue biopsy for each patient for use across separate assay platforms.

In addition to identifying the interchangeable use of independent anti-PD-L1 assay platforms an advantage would be to be able to substitute different antibody clones within the same assay detection platform. Neuman et al. investigated the use of the Dako clone 22C3 by IHC staining on the Ventana detection platform (16). Forty one cases of NSCLC were independently evaluated by two pathologists for PD-L1 expression and the same results were obtained by both platforms for 35 samples. Low intra- and intra-observer variation was recorded and the study concluded that the Dako 22C3 antibody clone could be used in facilities housing the Ventana platform.

In this analysis the authors compared three well validated diagnostic assays. Potentially there is greater value in assessing other commercially available, less well validated, antibodies such as E1L3N or the Ventana SP142. E1L3N (Cell Signaling Technologies) anti-PD-L1 antibody has recently been directly compared to Ventana SP263 (17) on a TMA containing 100 formalin fixed paraffin embedded (FFPE) NSCLC cores. The cores were analysed by two pathologists in a blinded study and PD-L1 staining patterns showed that the SP263 assay was more sensitive and had a wider dynamic range than the E1L3N assay. This type of research is useful to develop increasing access to PD-L1 staining techniques.

An industrial-academic collaboration is already underway with the aim to standardise PD-L1 IHC assays used in clinical trials (18). The Blueprint PD-L1 IHC assay comparison project recently published results from Phase 1 of the project where 39 NSCLC tissue samples were stained with anti-PD-L1 antibody clones 22C3, 28-8, SP142 and SP263. Although only in a small number of samples; importantly, PD-L1 expression was scored on both tumor and immune cells at any intensity. Variability across assays was increased for immune cells positivity than for tumor cell expression. The 22C3, 28-8 and SP263 were all comparable assays, as confirmed here by Ratcliffe et al. whereas the Ventana SP142 antibody exhibited fewer positively stained cells than the other clones.

Interestingly, Ratcliffe et al. found the variability was higher between two scoring pathologists than across IHC assays by a single scorer. The variability between scorers increased at PD-L1 expression levels below 10% of the tissue with an OPA between the original study pathologist and the independent pathologist decreasing from 95% at a cut-off level of ≥50% down to 76% at ≥1%. The authors assign this to the scorers’ perception of expression levels. This is an important finding as patients whose tumors have been categorized as PD-L1 negative continue to respond to anti-PD-1 therapies and therefore any incidence of a false negatives need to be ruled out. PD-L1 on other immune cells, PD-L2 expression and even the presence of PD-1
expressing immune cells may all be contributing factors in increasing confidence in biomarkers for therapies targeting the PD pathway. Calles et al. investigated the expression of PD-1 and both ligands, PD-L1 and PD-L2, in 114 patients with KRAS-mutant NSCLC (19). PD-L1 expression, but not PD-L2, was associated with smoking status. Another novel approach, by Paulsen et al., measured stromal PD-1 and PD-L1 in 536 NSCLC patient samples (20). PD-L1 positive immune cells within the stromal compartment and intraepithelial tumor-infiltrating lymphocytes expressing PD-1 were identified as independent positive prognostic factors in NSCLC.

Overall this research draws attention to the importance of graded PD-L1 positivity scores for combinational therapies. PD-L1 expression doesn’t conform to established predictive biomarkers where a beneficial treatment effect is expected between biomarker positive and negative patients. PD-L1 expression is heterogeneous and alters over time during an evolving immune response depending on concurrent or prior treatments such as chemotherapy and radiotherapy. As a result, challenges arise when using patient archival tissue samples. PD-L1 negative patients can also benefit from, and show responses to, anti-PD-1/ PD-L1 therapies. More detailed analysis of the tumor microenvironment may provide answers in these PD-L1 negative patients. Indeed, localization of PD-L1/PD-1 within tumor compartments adds to the complexity of its use as a biomarker. To conclude, these data suggest harmonization in PD-L1 assays is achievable with the caveat that additional scorers, with sufficient training, rather than the choice of antibody clone would provide higher assay validity and reproducibility across laboratories.
