In The Journal of Clinical Oncology, Ying Cheng and colleagues (1) have recently reported the results of a phase II randomized trial comparing pemetrexed plus gefitinib vs. gefitinib in treatment-naive, East Asian patients, with advanced non-squamous non-small cell lung cancer (NSCLC) and activating epidermal growth factor receptor (EGFR) mutations. The study met its primary end-point in the intent-to-treat population, showing a significantly longer median progression free survival (PFS) in favors of the combination arm (15.8 months) compared to single agent arm (10.9 months) [hazard ratio (HR): 0.68; 95% CI, 0.48 to 0.96; one-sided P = 0.014; two-sided P = 0.029]. The significant improvement in PFS was independent from the specific type of mutation (EGFR exon 19 deletion vs. EGFR exon 21 L858R point mutation). The addition of pemetrexed to gefitinib resulted also in a significantly longer time to progressive disease (16.2 vs. 10.9 months; HR: 0.66; 95% CI, 0.47 to 0.93) and duration of response (15.4 vs. 11.3 months; HR: 0.74; 95% CI, 0.50 to 1.08), while no differences in response rate (RR: 80% vs. 74%) were observed between the two treatment arms. As attended, the percentage of patients who reported grade 3-4 drug-related adverse-events (AEs) was significantly higher (42% vs. 19%) in the combination arm, as well as the proportion of patients who discontinued treatment because of AEs nearly doubled with pemetrexed plus gefitinib compared to single agent arm.

Several randomized phase III studies (2-10) previously showed that EGFR-tyrosine kinase inhibitors (TKIs) significantly improve both RR, PFS and quality of life (QoL) compared to platinum-based doublets chemotherapy as first-line treatment of EGFR-mutated NSCLC patients. Subsequently a pooled analysis of both LuxLung3 and LuxLung6 trials has also shown an overall survival (OS) benefit in favor of the EGFR-TKI Afatinib, even if it was limited to the subgroup of patients with EGFR exon 19 deletion (9). Overall, the results of all such studies convincingly and consistently demonstrated that for the subgroup of patients whose tumors harbor an EGFR activating mutation, the optimal strategy is starting with an EGFR-TKI, including gefitinib, erlotinib, or afatinib (11,12).

The trial conducted by Ying Cheng and colleagues (1) suggests that the addition of chemotherapy to the EGFR-TKI may further improve the outcomes of EGFR-mutated, non-squamous NSCLC patients.

Pre-clinical studies have shown a potential synergism between the EGFR-TKI, erlotinib, and the multi-targeted antifolate pemetrexed in NSCLC cell-lines (13,14). The modulation of both EGFR and Akt phosphorylation, together with a significant decrease of thymidylate synthase (TS) expression and activity in all NSCLC cells, represent the molecular mechanisms underlying such synergistic interaction. Later, early phase I-II studies demonstrated both a promising activity and a tolerable safety profile of EGFR-
TKI plus pemetrexed combination in pre-treated NSCLC patients (15), with a significantly longer PFS compared to either drug alone in a clinically selected population of never-smokers with non-squamous histology (16).

Several phase III studies investigated the efficacy of EGFR-TKI in combination with chemotherapy in first-line treatment (17-20), showing no survival benefit with combinations, likely because wild-type patients were also enrolled. Among these, CALGB30406 study (21) evaluated erlotinib with and without platinum-chemotherapy in clinically selected patients with advanced lung adenocarcinoma who were never or light former smokers, showing similar efficacy between the two treatment arms in the overall study population. A subsequent EGFR-mutation analysis revealed that patients with EGFR-positive tumors were most likely to benefit, reaching a median PFS of 14.1 months, and OS of 31.3 months with erlotinib, even higher (PFS: 17.2 months, OS: 38.1 months) in the combination arm. Such data suggested that EGFR-TKIs synchronously combined with chemotherapy could improve survival in molecular selected subsets of patients. Similarly the FASTACT2 randomized phase III study (22) also showed a survival benefit of a first-line intercalated regimen of chemotherapy and erlotinib in EGFR-mutated NSCLC patients.

Recently the NEJ005 randomized phase II study (23) prospectively compared concurrent gefitinib plus carboplatin/pemetrexed regimen vs. sequential alternating regimen in East-Asian, EGFR-mutated NSCLC patients. The results of such study showed a favorable trend in PFS (18.3 vs. 15.3 months; HR: 0.71; 95% CI, 0.42–1.20; P=0.20) and a significant improvement in OS (41.9 vs. 30.7 months; HR: 0.51; 95% CI, 0.26–0.99; P=0.042), in favor of the concurrent regimen arm, first demonstrating the superiority of the upfront combination of gefitinib and carboplatin/pemetrexed, which is currently investigated in the ongoing phase III NEJ009 study. The trial conducted by Ying Cheng and colleagues (1) suggested that adding single-agent chemotherapy to EGFR-TKI in first-line may be sufficient to improve outcomes of EGFR-mutated patients. The results are intriguing, but need to be interpreted in light of the recent NEJ005 study. The PFS improvement is consistent across both studies, and is more favorable in comparison to the 9–10 months PFS observed in previous studies of first-line gefitinib monotherapy in EGFR-mutated NSCLC patients (2). It could be likely related to the activity of early concurrent use of cytotoxic agents against de-novo resistance alterations, but the lack of tissue samples collection for biomarker analysis, limited the possibility to evaluate molecular data. However, it will be important to see whether the addition of pemetrexed to gefitinib will also lead to an OS benefit. Indeed, OS improvement is crucial in order to evaluate the optimal treatment sequence in this setting of patients, and ultimately accept the increased adverse events and cost of a potential upfront combination. Even if authors declare that “platinum-based therapies may still be used after progression", the patients included in the experimental arm will never receive the standard treatment option, which is platinum-pemetrexed combination followed by pemetrexed maintenance therapy (24), and this could negatively affect their final OS.

Furthermore we need to discuss the clinical benefit obtained with chemotherapy plus gefitinib combination considering the other promising treatment option emerging in this setting.

The addition of bevacizumab to the EGFR-TKI, Erlotinib, reached a median PFS: 16 vs. 9.7 months of erlotinib monotherapy, with about 50% significant reduction of the risk of progression [HR: 0.54 (0.36–0.79)], in East-Asian, EGFR-mutated patients (25). Waiting for the randomized phase III studies currently ongoing both in Asian and Caucasian populations, such combination has recently received the approval by both Food and Drug Administration (FDA) and European Medical Agency (EMA) as first-line treatment. Even more exciting are the data emerging from the first-line cohort of AURA phase I trial (26), which showed an impressive activity of the third generation EGFR-TKI osimertinib, with a median PFS: 19 months and an ORR: 77%, leading to the ongoing phase III randomized FLAURA trial comparing osimertinib vs. gefitinib/erlotinib in first-line. Despite immunotherapy with anti-PD1/PDL1 single agent seems to be not effective in NSCLC harboring EGFR-mutations (27), several trials are currently investigating potential combinations of checkpoint-inhibitors with EGFR-TKI, in order to further improve the outcomes of these patients.

In conclusion the study of Cheng et al. represent a significant attempt to the improvement of first-line treatments for EGFR-mutated NSCLC patients. The PFS benefit together with a modest increase in toxicity suggest that adding chemotherapy to EGFR-TKI may represent an effective treatment option in this setting. However, as mentioned before, OS benefit is crucial in order to confirm the effectiveness of Pemetrexed plus Gefitinib upfront combination. Finally, considering the advent of new
promising drugs/combinations, the main challenge will be how to combine all these agents and ultimately define the optimal treatment sequence for EGFR-mutant NSCLC patients.
