Abstract: Breast cancer (BC) metastasis accounts for the majority of deaths from BC. The rate of metastasis to uncommon sites is on the rise due to the more effective therapy prolonging survival and to the early detection on imaging. The evaluation of patient-reported symptoms is essential in detecting a recurrence as early as possible, which may impact survival. Hence, the knowledge of even the rare sites of BC metastasis is of paramount importance for the clinical interpretation of new symptoms in BC survivors. The term “unusual metastasis” defines a systemic failure with a frequency of $\leq 1\%$ at each site and according to this unusual metastasis involve the central nervous system, secretory/endocrine organs and glands, internal organs and structures, and gynecological organs. The literature search was performed using the electronic database PubMed up to December 2018, with the following key words: {[rare(Title/Abstract)] OR [unusual(Title/Abstract)] OR [unconventional(Title/Abstract)]} AND {[metastases(Title/Abstract)] OR [metastasis(Title/Abstract)]} AND {[breast(Title/Abstract)]} AND {[cancer(Title/Abstract)] OR [tumor(Title/Abstract)] OR [tumour(Title/Abstract)] OR [neoplasm(Title/Abstract)]}. The search was limited to papers in English language. Of the 3,086 papers found, 757 were excluded as reporting animal models, 378 were not in English language, 1 was a duplicate of the same research, 1,414 did not report on BC metastases, 108 were previous review reviews on BC or tumour to tumour metastases; 428 papers were included in this review. Despite the improvements in BC management, most deaths from cancer result from metastases that are resistant to conventional therapies. In general, it is uncommon to find isolated rare metastases, the vast majority of these develops together with metastases in other sites, thus highlighting a worsening systemic disease. However, the early detection of even rare metastases represents the only chance to control the disease and prolong survival while waiting for the development of more effective systemic therapies.

Keywords: Breast cancer (BC); rare metastasis; unusual site; metastatic disease

Introduction

Breast cancer (BC) metastasis accounts for the majority of deaths from BC. The rate of metastasis even in sites known as uncommon is on the rise. On one side this is due to the more effective therapy which have prolonged the overall survival of BC patients, on the other side due to the development of new imaging techniques and early detection (1). The American

Cancer Society/American Society of Clinical Oncology Breast Cancer Survivorship Care Guideline recommends that primary care clinicians should educate and counsel all women about the signs and symptoms of recurrence, including new lumps, pain in the bone, chest or abdomen, dyspnea and constant headaches (2). There is no evidence that routine laboratory tests or imaging (exception for mammography, when indicated) in asymptomatic patients gives any survival

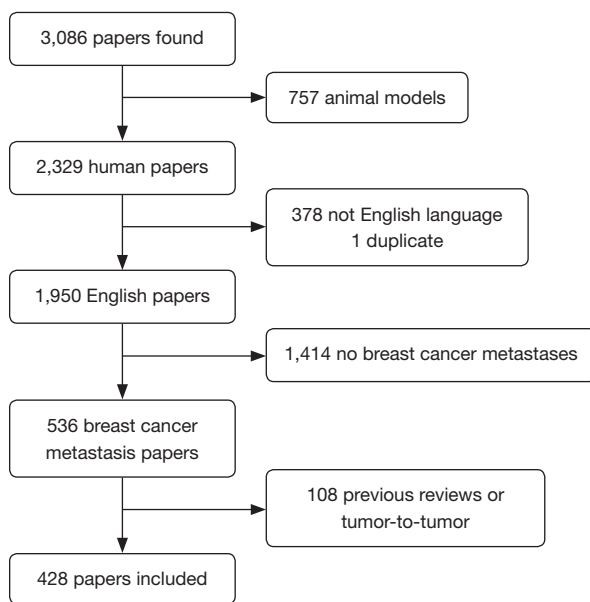

Figure 1 Flow chart of studies included in the review.

advantage, thus advanced imaging should be offered when recurrence is suspected (3,4). The evaluation of patient-reported symptoms is essential in detecting a recurrence as early as possible, which may impact survival (5,6). Hence, the knowledge of even the rare sites of BC metastasis is of paramount importance for the clinical interpretation of new symptoms in BC survivors.

BC can metastasize to several organs, the most frequent metastatic sites include bone, lungs, liver and skin (7). Additionally, more and more sites of BC metastasis have been reported in literature. The definition of “unusual metastasis” is not universally accepted, however it defines a systemic failure with a frequency of $\leq 1\%$ at each site and according to this unusual metastasis involve the central nervous system, secretory/endocrine organs and glands, internal organs and structures, and gynaecological organs.

This review reports on the rare anatomical regions where BC can spread forming metastases.

Methods

The literature search was performed using the electronic database PubMed up to December 2018, with the following key words: $\{[rare(Title/Abstract)] \text{ OR } [unusual(Title/Abstract)] \text{ OR } [unconventional(Title/Abstract)]\} \text{ AND } \{[metastases(Title/Abstract)] \text{ OR } [metastasis(Title/Abstract)]\} \text{ AND } \{[breast(Title/Abstract)]\} \text{ AND } \{[cancer(Title/$

$Abstract)] \text{ OR } [tumor(Title/Abstract)] \text{ OR } [tumour(Title/Abstract)] \text{ OR } [neoplasm(Title/Abstract)]\}$. The search did not include editorials, letters, comments, conference letters, systematic reviews and meta-analyses and it was limited to papers in English language.

All studies on rare sites of metastases from BC were eligible to be included.

All data were extracted in a standard pre-determined format including information on: first author’s name, publication year, number of cases and site of metastases. We considered rare the sites different from nodes, bone, lung, liver and skin.

Results

The flow chart of the study selection was shown in *Figure 1*. Of the 3,086 papers found, 757 were excluded as reporting animal models, 378 were not in English language, 1 was a duplicate of the same research, 1,414 did not report on BC metastases, 108 were previous review on BC or tumour to tumour metastases, 428 papers were included in this review. *Table 1* shows the distribution per sites of all cases of rare metastases reported in literature.

Discussion

In the war against BC, metastasis remains a primary clinical challenge as it is unpredictable in onset and it exponentially increases the clinical impact to the patient. The process of tumour metastasis is still controversial. Starting from Paget’s hypothesis of “seed and soil” (436), numerous studies have partially confirmed his observations and integrated new findings with the idea of a multistage process dependent on both the intrinsic properties of the tumour cells and the host response (437). In 1889 the surgeon Stephen Paget had already raised the question of “What is that decides what organs shall suffer in a case of disseminated cancer?” and contradicted the prevailing theory of Virchow (438) on metastasis originating from the arrest of tumour-cell emboli in the vasculature. Paget’s hypothesis is now widely accepted and enriched by new studies. The current definition of “seed” is a progenitor cell, cancer stem cell, or metastatic cell within the heterogeneous subpopulations forming the primary tumour, and the “soil” is the host factor, stroma, niche or organ microenvironment where selected metastatic cells can live and grow (439,440).

Translating Paget’s theory into clinical practice, findings show that BC preferentially spreads to some organs, whilst

it is less common to find BC metastasis in other remote sites. In this review we mainly focused on anatomical sites where few cases of metastases have been reported in literature.

In clinical practice the knowledge of common sites of metastases helps the physician to detect early symptoms corresponding to secondary lesions, however when BC metastasizes in less expected sites the diagnosis could be delayed.

BC is amongst the most common tumours to metastasize to the head and neck, it constitutes ~15–20% of all metastases to this region and has been described in almost every head and neck anatomic subsite. However, since metastases to the head and neck are uncommon to begin with, breast carcinoma metastases are still relatively rare in clinical practice. Parenchymal metastases to

the submandibular and parotid glands can be difficult to distinguish from new primary tumors arising there, specifically salivary duct carcinoma. In these cases immunohistochemistry only can help differential diagnosis (15). Among metastatic orbital neoplasms, BC is the most common primary tumour, in particular, 55 cases were reported as affecting orbital soft tissue and 55 cases choroid, being bilateral in less than 1% of cases (1/55). A median time to onset of orbital metastases from BC diagnosis is 4.5–6.5 years and the majority of these patients have ER positive Her2 positive BC. A biological explanation for this tropism might be that steroid hormones, needed for tear production are produced in the orbital fat or in alternative, orbital metastases could be a late complication in patients with slow growing ER positive disease (17). Whether there is a tropism of lobular cancer cells to the orbital tissue or this is

purely due to the more infiltrative nature of this tumor type along with its general tendency for spreading to myriad body sites is a matter of speculation (18). Prognosis in cases of orbital metastases from BC is determined by metastatic burden. A mean survival time of 5–22 months after orbital diagnosis has been reported in the literature. Furthermore, orbital metastases can cause various local problems, such as exophthalmos, exposure keratitis, optic neuropathy, and limited extraocular muscle motion. As enucleation confers no benefit in terms of survival, external beam radiotherapy is the most commonly used palliative treatment (16). Although BC rarely metastasizes to the head and neck region, awareness should be raised when BC patients experience headache or have sinus-related symptoms. The most of these patients have very poor prognosis, however chemotherapy and radiotherapy may be effective to prolong survival (126). Despite the principle that metastatic deposits have a predilection for highly vascularized organs, the thyroid is rarely a metastatic site. We found 39 cases of BC metastasis to the thyroid gland reported in literature, the true prevalence oscillates from 3% to 34% of all thyroid metastases, whilst it is much more common to find synchronous or metachronous malignancies (84,170–187). The suspicion of metastatic disease should be raised by thyroid lumps in BC survivors, although indicating poor prognosis, the role of surgery in these lesions should be considered for local disease to control, palliate and prevent the potential morbidity on the airway (441,442).

Despite the well-known BC propensity to spread to the central nervous system, the prevalence of symptomatic central nervous system metastases among patients with BC ranges from 5% to 16%, although autopsic studies have reported prevalence rates of up to 30% (414). In our review we found 18 cases of intramedullary spinal cord metastases (see *Table 1*). The mechanism of intramedullary spread is not well established but it may involve lymphatic or haematological transit, direct spread from the vertebrae or ‘drop-down’ metastases from the brain. The most common symptoms are paresis and dysesthesia or bladder dysfunction, both surgery and radiotherapy are recommended both for diagnosis and treatment of brain metastases (405). Interestingly, Zebrowski *et al.* (407) suggested a potential association between the inability of trastuzumab to cross the blood-brain barrier and the occurrence of intramedullary metastases in Her2 positive disease. Additionally, some studies report a predisposition of lobular histotype to leptomeningeal carcinomatosis, whilst in the case of ductal carcinoma spreading to the meninges a high

histological grade and triple-negative biology seems to be prevalent (394).

Although very rare (9 cases reported), metastasis to the spinal nerve root ganglion can be the first manifestation of distant hematogenous metastases of BC. The clinical course is characterized by increasing radicular symptoms-especially intractable pain. Surgical intervention with tumour debulking followed by radiotherapy provides local tumour control and palliation from pain (422–425).

Soft tissue metastasis from any primary malignancy is considered very rare, it can be in subcutaneous and muscular tissue (117). In this review we found 33 cases of soft tissues metastases involving skeletal muscle or subcutaneous tissue or both of the upper and lower limbs, trunk, shoulders, and buttocks (117–120). Some studies have reported a frequency of 0.8% based on autopsies while few reported an incidence of 0.2% based on clinical studies (443,444). This rarity can be due to the fact that soft tissues produce anti-carcinogenic factors like lactic acid, beta adrenergic receptors or protease inhibitors which serve as a deterrent for metastatic invasion (116,445,446). As for other metastatic sites a multimodality approach generally is adopted depending upon the performance status of the patient, any comorbid condition, type of primary malignancy, site and size of the metastatic lesion. RT and chemotherapy have been generally considered the primary modality of therapy either in combination or separately while surgery is reserved for patients not responding to radiation or chemotherapy. A high degree of clinical suspicion and immuno-histopathological confirmation are required to identify and diagnose any soft tissue swelling of the body in a previously treated primary breast cancer patient to prevent any inappropriate treatment causing undue morbidity or even mortality (117).

Gastrointestinal (GI) tract metastases from BC are also considered rare, their incidence in autopsy series varied from 8% to 35% (274,447). This localization can easily simulate a primary GI cancer and any region of the GI tract can be involved, from the tongue (145) to the anus (448). Most series report a greater propensity of lobular carcinoma to metastasize to the GI tract and peritoneum, but data on this tropism are poor and inconclusive (231,449,450). The most common site of GI tract metastasis is the stomach, 185 cases in our review. Colon involvement is quite common (59 cases), whilst small intestine involvement has been reported in 24 cases and is more frequently diagnosed at autopsy. In particular, ductal carcinoma seems to produce nodular stomach lesions, while lobular BC tend to cause

more diffuse disease (451). The GI tract metastases are uncommon and peculiar, the main issue is to identify symptoms like nausea, vomiting, diarrhoea or abdominal pain and start the differential diagnosis with CT scan, endoscopy and biopsy. According to literature reports, surgery is crucial when possible, nevertheless chemotherapy and endocrine therapy were commonly used, very rarely radiotherapy can also play a role (452). Other abdominal organs are also rare sites of BC metastasis often mimicking primary tumours, so the final diagnosis occurs after biopsy or surgical excision.

BC metastases can also involve genital organs and the placenta. Most cases of uterine metastases presents as vaginal bleeding or abdominal discomfort, although the vast majority of these have been diagnosed during autopsy (78,453). Studies have showed that the incidence of ovarian metastases in BC patients is 13–47%. It seems that the metastatic lesions reach the ovaries and genital organs through the lymphatic and blood vessels, or through trans-coelomic spread, then the reciprocal interaction between intrinsic BC molecular characteristics and the local microenvironment explains the metastatic organotropism (103,454). The most common sign of uterine or vaginal metastases is vaginal bleeding, while ovarian metastases frequently present as an asymptomatic ovarian mass (455,456). In any case, the central task is to differentiate primary versus secondary tumours, as this will affect the clinical decision process, treatment and prognosis. The surgical metastasis excision, hysterectomy or oophorectomy not only provide diagnostic information, but they could also have a curative effect along with systemic therapy (104). The local control of bleeding can also benefit from radiation therapy, uterine artery embolization and conisation (73). However, genital tract and ovarian metastases represent the late stage of a systemic disease, for instance BC patients with ovarian metastases have a 6–26% 5-year survival rate (106,454,457). The lack of symptoms and poor outcomes emphasize the relevance of a regular gynaecological surveillance in all BC survivors, despite guidelines citing different approaches (73). In 2003, Alexander *et al.* (108) have reported the most comprehensive review of placental involvement (15 cases), where BC cells were located in the intervillous space without any involvement of the fetal villous stroma and vascular circulation. Fetal immune response seems to play a key role in avoiding the fetal involvement when possible, although maternal prognosis remains very poor (109,110). Malignant disease in pregnancy provoke a challenging

situation for gynaecologists, breast surgeons, oncologists and neonatologists, all placentas should be evaluated by pathologists and each single case of metastasis should be discussed within a multidisciplinary team (109).

The analysis of BC metastatic pattern has shown that lobular tumours were more likely to metastasize to the peritoneum, adrenal glands, uterus and pleural surface (458). Additionally, the aggressiveness of lobular carcinoma seems to be associated to metastasis at unusual sites, in particular meningeal dissemination was more frequently associated to lobular BC (459–462). A retrospective study on 3783 patients about the distribution and frequency of metastases at unusual sites showed that the majority of unusual metastases are associated with prior metastases at more unusual sites, which appear, on average, 1 year before. The prognosis of metastatic BC patients was the same irrespective of the metastasis site and no risk factors for unusual metastasis were identified (84). In general, it is uncommon to find isolated rare metastases, the vast majority of the rare metastases described develop together with metastases in other sites, thus highlighting a worsening systemic disease.

Conclusions

Despite the improvements in diagnosis, surgical techniques, general patient care, and local and systemic adjuvant therapies, most deaths from cancer result from metastases that are resistant to conventional therapies. The process of cancer metastasis is sequential and selective and incorporates stochastic elements, hence the growth of metastases represents the endpoint of the interplay of tumour cells with host factors.

On the research level, the recent advances in our understanding of the metastatic process at the cellular and molecular level provide unprecedented potential for the improvement and the development of effective adjuvant therapies.

On the clinical level, the early diagnosis of secondary lesions represents the only chance to control the disease and prolong survival, hence the knowledge of the common as well as rare sites of metastases can help the physician to detect symptoms and plan the most appropriate treatment.
